PROBLEM FORMULATION

1.1 INTRODUCTION

N-queen problem:

The eight queens puzzle is the problem of placing eight chess queens on an 8×8 chessboard so that no two queens threaten each other. Thus, no two queens should share the same row, column, or diagonal.

For example- The solution for 8-Queen problem looks something like this.

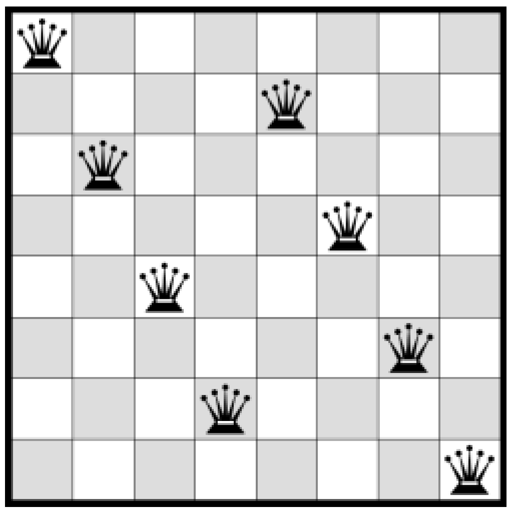

Fig 1- Solution of 8-queen problem

Hill-climbing:

This algorithm is simply a loop that continually moves in a direction of increasing value- uphill. It terminates when it reaches the peak where no neighbor has the highest value. The algorithm does not maintain a search tree and therefore only record the state and the value of the objective function.

PROGRAM STRUCTURE

2.1 Introduction

Number of queens are treated as N variable and input can enter the value N. Following 3 are implemented

1) Steepest-ascent hill climbing

2) Hill-Climbing with sideways move

3) Random-restart hill-climbing with and without sideways move The N-queens problem is described below by an example.

The N Queen is the problem of placing N chess queens on an N×N chessboard so that no two queens attack each other.

2.2 Functions and Procedures

- def __init__(self, queen_positions=None, queen_num=8, parent=None, path_cost=0, f_cost=0, side_length=8) – it's the path constructor for the the QueenState.
- random_position(self) – placing each queen in a random row in a different column.
- get_children(self) - fetching all the possible queen moves.
- random_child(self) – selecting random child for allow sideways move algorithm
- queen_attacks(self) – queen to check for attacking queen
- num_queen_attacks(self) – reporting violation
- __init__(self, start_state=None) – default constructor for initial board
- goal_test(self, state) – check if goal state is attained
- cost_function(self, state) – calculate number of violation
- avg_steps(result_list, key) – calculate the average number of steps needed
- print_data(results) – prints result of all the hill climbing algorithm
- print_data_row(row_title, data_string, data_func, results) – print data row wise
- print_results(results) – print results

- analyze_performance(problem_set, search_function) – function takes problem set and calls passed (parameter) search function and calculates steps
- analyze_all_algorithms(problem_set) – function to solve problem with steepest ascent, steepest ascent 100 sideway moves, random restart and random restart 100 sideways move
- steepest_ascent_hill_climb(problem, allow_sideways=False, max_sideways=100) – steepest ascent hill climbing with and without sideways

2.2 Global and Local variables

Local variables-

- queen_positions
- queen_num
- parent
- path_cost
- f_cost
- side_length
- parent_queen_positions
- random_queen_index
- attacking_pairs
- start_state
- result_list
- results
- num_iterations
- section_break
- freq
- queens_problem_set
- children
- children_cost
- min_cost
- node
- node_cost
- sideways_moves
- path
- best_child
- best_child_cost
